

ARIMA Time Series Analysis of Telecom Revenue

Tucker Atwood, WGU MSDA

2024-06-05

A1. Research Question

Using the provided churn time series data of telecommunications revenue by firm, I will answer the question, "Can an ARIMA time series model be used to forecast future telecom revenue?"

A2. Analysis Goal

The goal of this analysis is to develop an Autoregressive Integrated Moving Average (ARIMA) time series model capable of providing insight into telecom revenue patterns, so that predictions of future revenue may be made. While customer churn data is not provided for this analysis, the larger goal of the telecoms stakeholders is to decrease churn rate by analyzing associated factors. By developing an understanding of revenue patterns and using the insights to make predictions of future revenue, stakeholders will be better equipped to analyze the impact of customer churn on revenue.

B. ARIMA Assumption

The following assumptions are relevant to conducting an ARIMA time series model:

- The data must exhibit stationarity, which means the mean, variance, and autocorrelation remain relatively constant and do not change as a function of time. This implies that there must be no overall trend or seasonality in the data.
- The data must not be significantly autocorrelated, which means individual time values are not correlated with their prior values. This implies that all observations must be independent of each other.
- If there is evidence that either of these assumptions are not met, a method of differencing the data may be used to remove trends and make the data stationary.

C1. Time Series Visualization

To prepare the data for ARIMA analysis, a visualization of the time series data will first be inspected. To prepare this visualization, the following steps will be taken. Note: All input and output code included in this report will be provided in the language R:

```
# Imports data set
df <- read.csv("C:/Users/atwood/OneDrive/Desktop/RMDA/Directory/telecom_line_series.csv")

# The necessary packages for analysis must be imported. The relevant packages are:
# series, which will allow the usage of the adf test function. This will perform an augmented Dickey-Fuller hypothesis test to determine stationarity.
# aetla, which will allow the usage of the mvspec function. This will perform the spectral density test to determine seasonality.
# forecast, which will allow the usage of the auto.arima and Arima functions. These will be essential to the selection and execution of the optimal ARIMA model.

# Imports packages to be used in analysis
library(series) # using series package to utilize adf test function

# Registered 33 method overwritten by 'quantmod':
# method from
# as.zoo.data from zoo

library(aetla) # using aetla package to utilize mvspec function
library(forecast) # using forecast package to utilize auto.arima and Arima functions

# Attaching package: 'forecast'

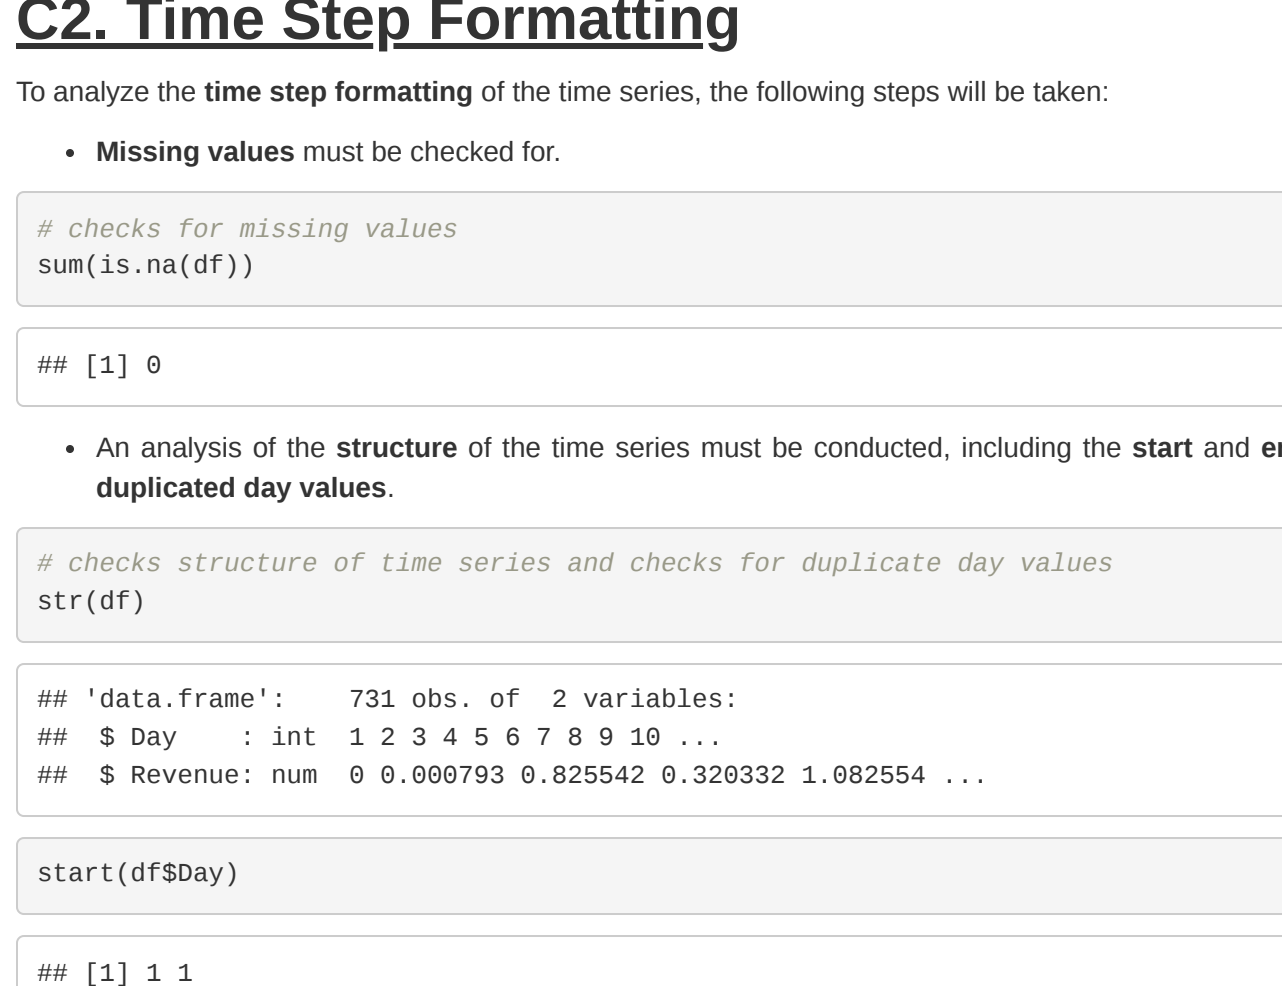

# The following object is masked from 'package:aetla':
# gas

# The data must be converted into a time series object, with a starting value of 1 and a frequency of 30 to represent monthly periods within the data.

# Converts data into a time series
ts <- ts(df$Revenue, start = 1, frequency = 30)

# The realization of the time series may now be visualized graphically.

# Generates time series plot, no noticeable outliers, trend upward linear (not stationary)
plot(ts, xlab = "Day", ylab = "Revenue", main = "Time Series: Day vs Revenue")
```

C2. Time Step Formatting

To analyze the time step formatting of the time series, the following steps will be taken:

- Missing values must be checked for.

```
# Checks for missing values
is.na(ts)

# [1] 0

# An analysis of the structure of the time series must be conducted, including the start and end of the series, as well as a check for any duplicate day values:

# Checks structure of time series and checks for duplicate day values
str(df)

# Data frame:      ts: 30 obs. of  3 variables:
# $ Day: int      1 2 3 4 5 6 7 8 9 10 ...
# $ Revenue: num  0 0.000793 0.820542 0.320332 1.00254 ...

start(df$Day)

# [1] 1

end(df$Day)

# [1] 731

sum(duplicated(df$Day))

# [1] 0
```

From the given outputs, the following can be determined:

- The length of the sequence is 731 days, which represents two years of data when one year is a leap year.
- There are no gaps in measurement, since there are 731 observations, the start of the sequence is 1, the end is 731, and there are no duplicates.
- Each observation represents one day of revenue for the telecommunications company, and the interval between observations, one day, is consistent throughout the data.

C3. Stationarity

To evaluate the stationarity of the time series, an augmented Dickey-Fuller (ADF) hypothesis test will be run on the data. The null hypothesis is that the data is not stationary, the alternative hypothesis is that the data is stationary, and the alpha level will be set to 0.01.

```
# runs augmented Dickey-Fuller hypothesis test
adf.test(ts)

# 
# Augmented Dickey-Fuller Test
# data: ts
# Dickey-Fuller = -3.0328, Lag order = 9, p-value = 0.02431
# alternative hypothesis: stationary

# The p-value of the ADF test is 0.0243. Since this is above the determined alpha level, there is not enough evidence to reject the null hypothesis, the data may not be stationary. This is also apparent in the above visualization of the time series, where a general upward trend is apparent.
```

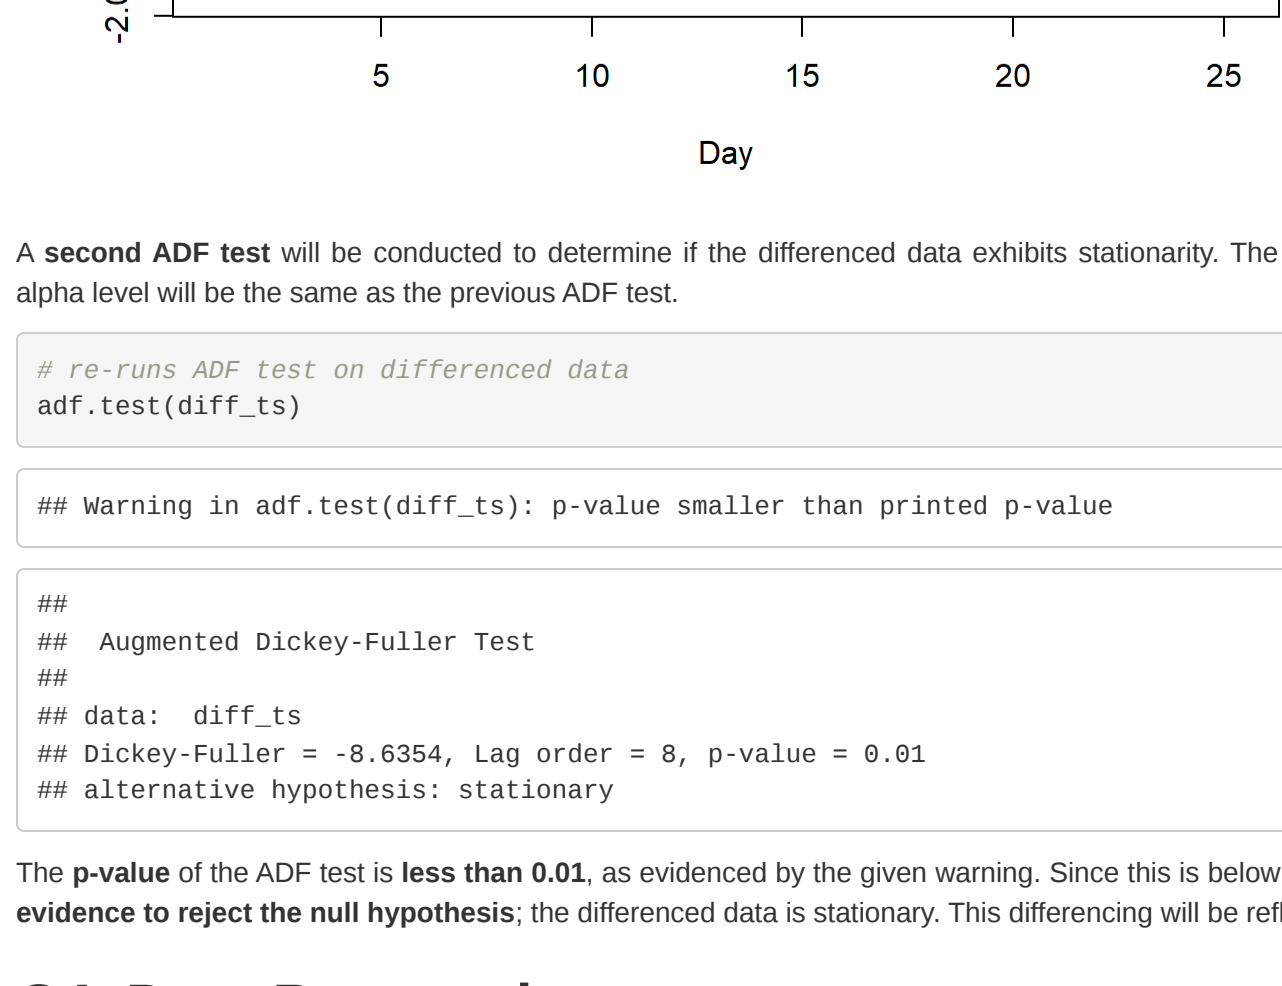

To correct the data to stationarity, the data will be differenced. This involves subtracting the previous value from each individual observation, which creates a time series of the changes between observations. This is also apparent in the above visualization of the time series, where a general upward trend is apparent.

```
# generates differenced time series
diff.ts <- diff(ts)
plot(diff.ts, xlab = "Day", ylab = "Difference", main = "Difference Plot: Day vs Difference")

# Difference Plot: Day vs Difference

# Difference Plot: Day vs Difference

# Difference Plot: Day vs Difference
```

A second ADF test will be conducted to determine if the differenced data exhibits stationarity. The null hypothesis, alternative hypothesis, and alpha level will be the same as the previous ADF test.

```
# runs ADF test on differenced data
adf.test(diff.ts)

# Warning in adf.test(diff.ts): p-value smaller than printed p-value

# 
# Augmented Dickey-Fuller Test
# data: diff.ts
# Dickey-Fuller = -8.4384, Lag order = 8, p-value = 0.01
# alternative hypothesis: stationary

# The p-value of the ADF test is less than 0.01, as evidenced by the given warning. Since this is below the determined alpha level, there is enough evidence to reject the null hypothesis, the differenced data is stationary. This differencing will be reflected in the selection of an ARIMA model.
```

C4. Data Preparation

To prepare the time series data for ARIMA analysis, the following steps were taken:

- The provided data set was converted into a time series object, which was performed in section C1.
- Missing values and duplicate values were checked for, which was performed in section C2. No missing values or duplicate values were found.
- The data will be split into a training set and testing set using an 80-20 ratio, with the first 80% of data, which represents 585 observations, included in the training set, and the last 20% of data, which represents 146 observations, included in the test set. This process was not randomized because the data is sequential and the test set will be used to analyze the ability for the ARIMA model to forecast future revenue values.

```
# creates the training and testing data sets (80-20)
train <- ts(df[1:585,])
test <- ts(df[586:731,], start = 586)
```

C5. Cleaned Data Sets

The resulting time series data will be written to CSV files and included as the following attachments:

- "clean_ts.csv" represents the full, cleaned time series data.
- "diff_ts.csv" represents the differenced time series data.
- "training_set.csv" represents the training time series data.
- "test_set.csv" represents the test time series data.

```
# writes CSVs of cleaned time series data, training set, and test set
write.csv(ts, "C:/Users/atwood/OneDrive/Desktop/RMDA/Directory/clean_ts.csv")
write.csv(diff.ts, "C:/Users/atwood/OneDrive/Desktop/RMDA/Directory/diff.ts.csv")
write.csv(train, "C:/Users/atwood/OneDrive/Desktop/RMDA/Directory/training_set.csv")
write.csv(test, "C:/Users/atwood/OneDrive/Desktop/RMDA/Directory/test_set.csv")
```

D1. Time Series Analysis

To analyze the time series data, the following analysis steps will be taken:

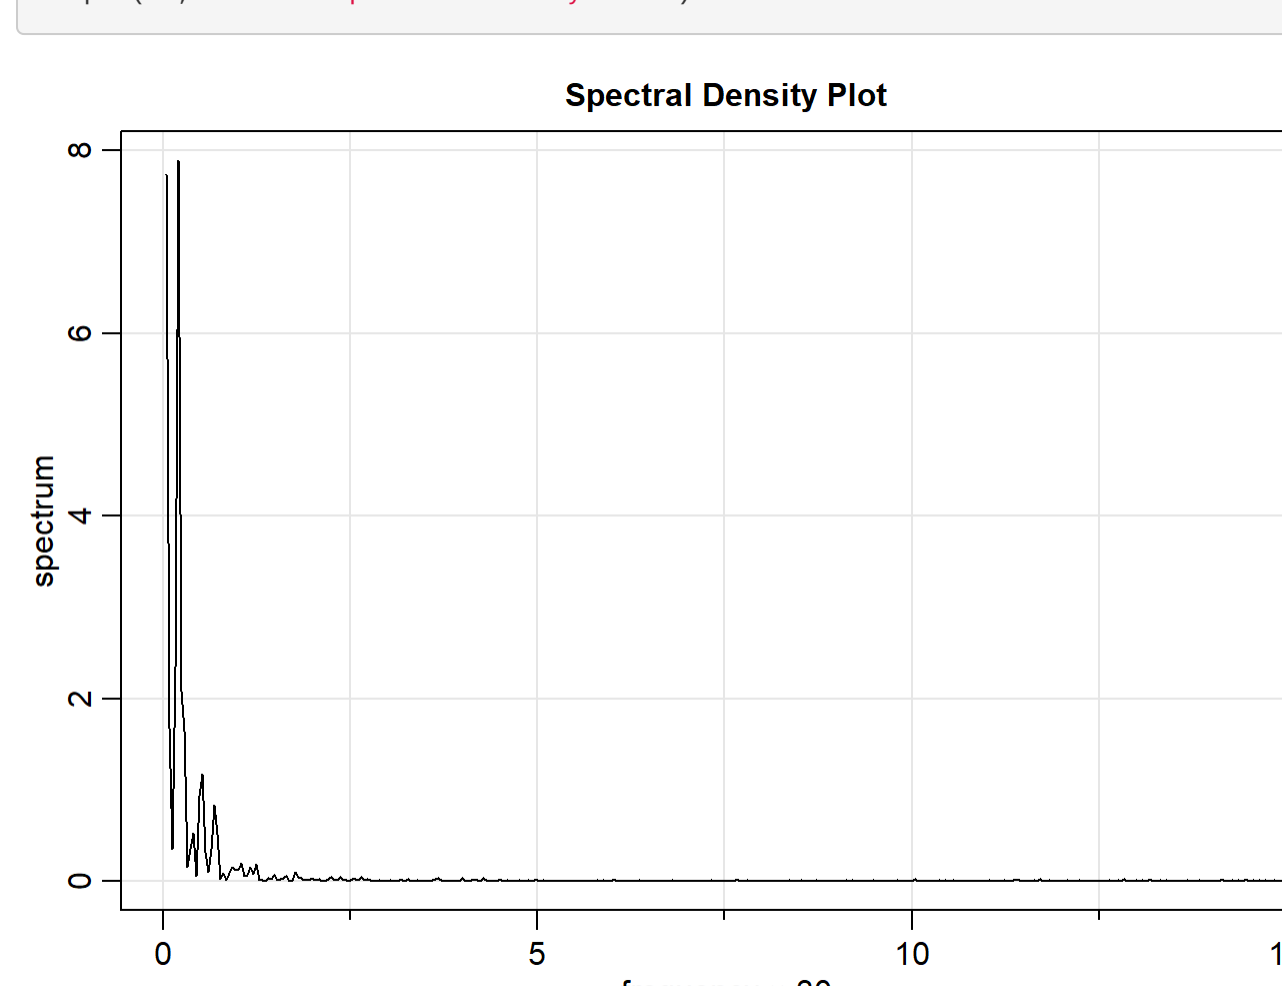

- An additive time series decomposition will be conducted. This involves a visualization of the trend of the data by calculating a rolling average. Removing the trend provides a seasonal component, which can be used to help determine whether the data exhibits seasonality. Removing the trend and seasonality leaves a remainder referred to as a random component. This represents the residuals of the decomposed time series. A lack of trends in the residuals confirms that the decomposed data shows no trend, seasonality, or autocorrelation.

```
# decomposes original data
decomp <- decompose(ts)
plot(decomp, xlab = "Months")

# Decomposition of additive time series

# Decomposition of additive time series

# Decomposition of additive time series
```

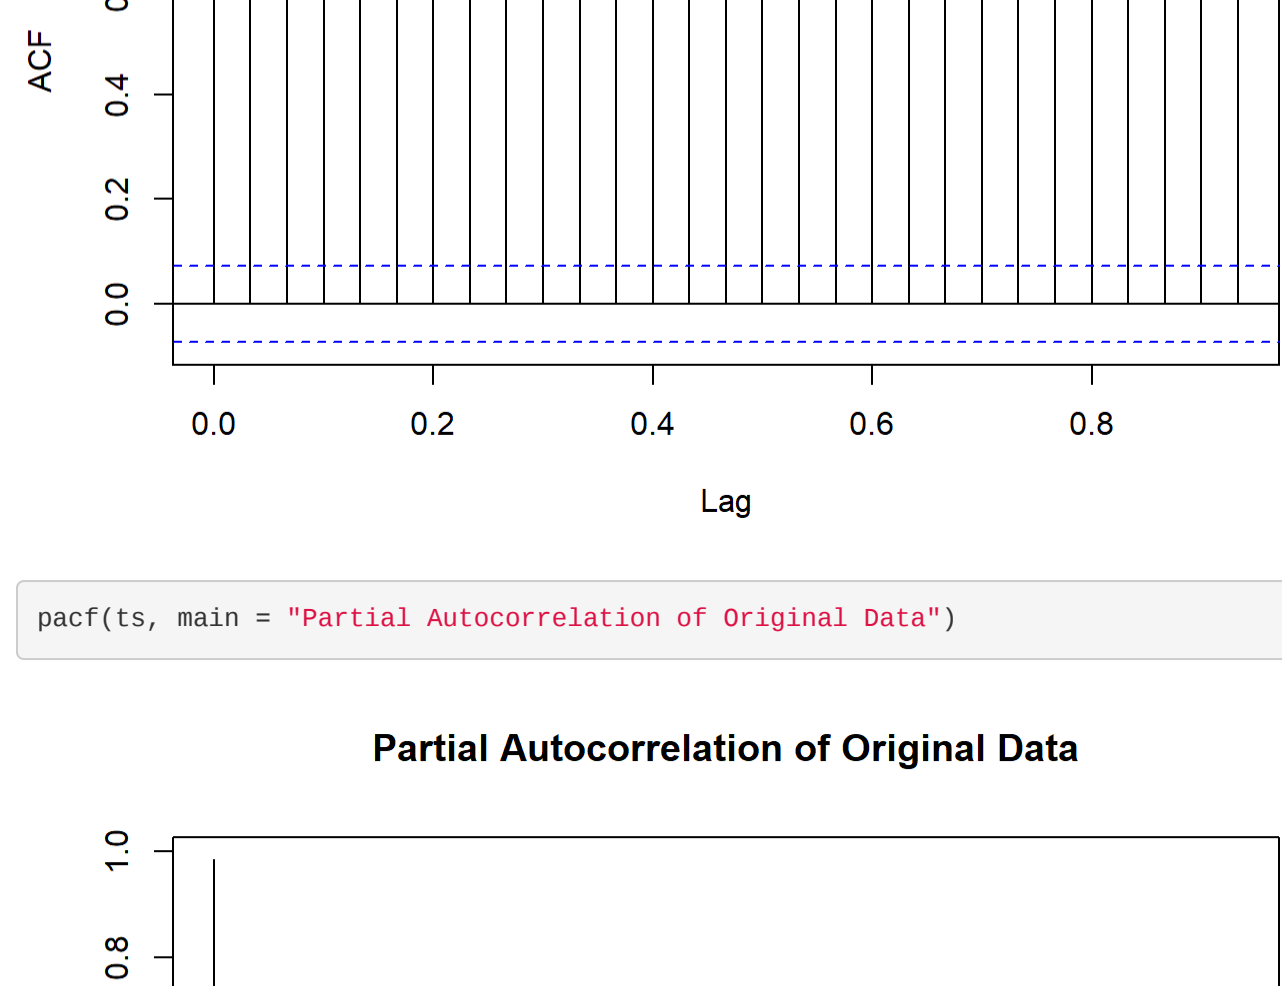

- From the above decomposition, the following analyses can be made:
- The magnitude of the seasonal component suggests there is no significant seasonality in the data.
- There is no apparent trend in the residuals.
- To further investigate potential seasonality in the data, a spectral density plot will be graphed.

```
# spectral density plot indicates no seasonality
spec.ts, main = "Spectral Density Plot")

# Spectral Density Plot

# Spectral Density Plot
```

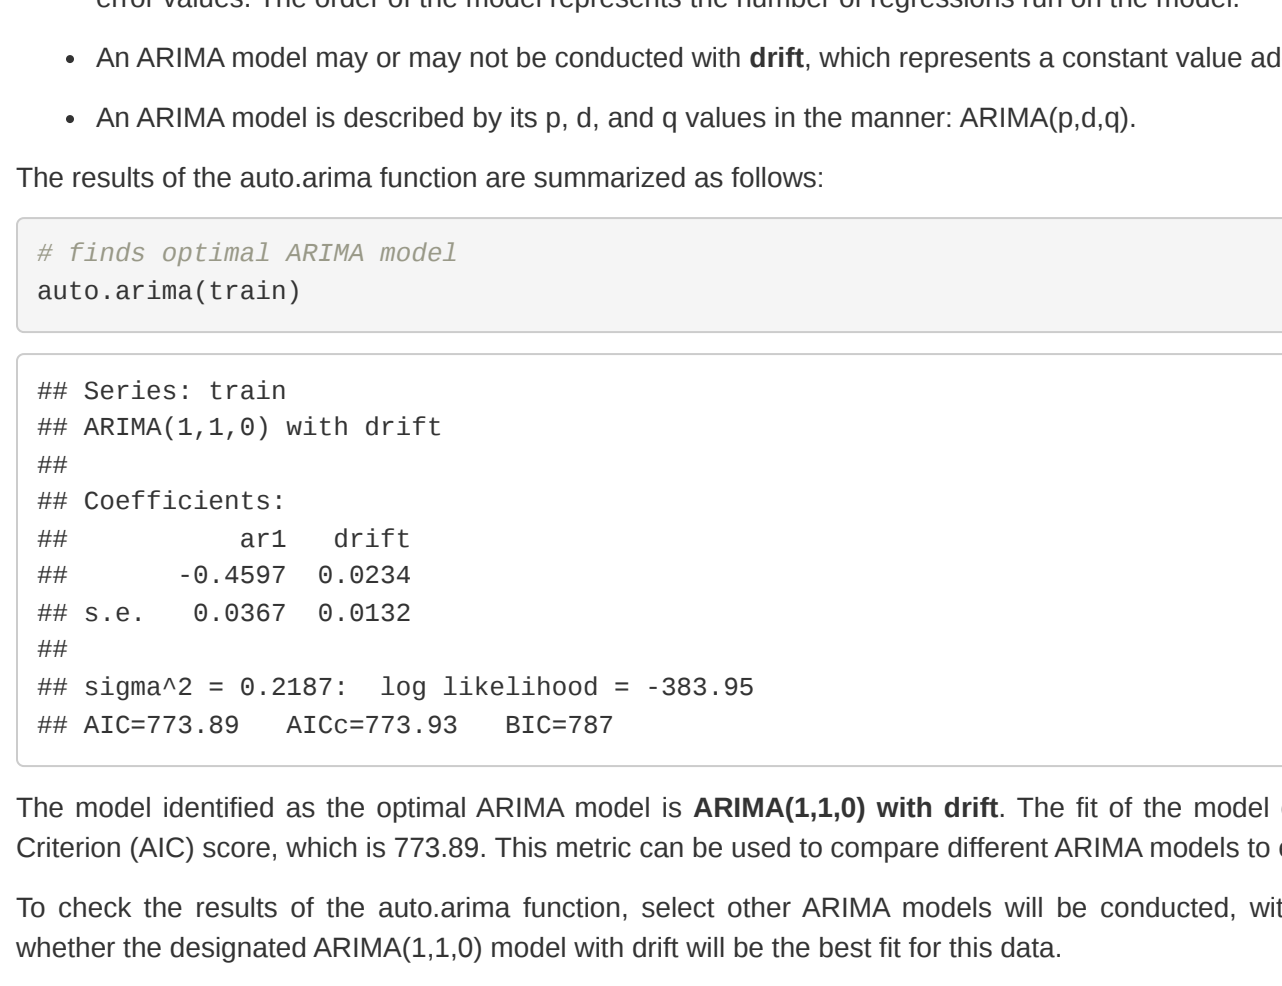

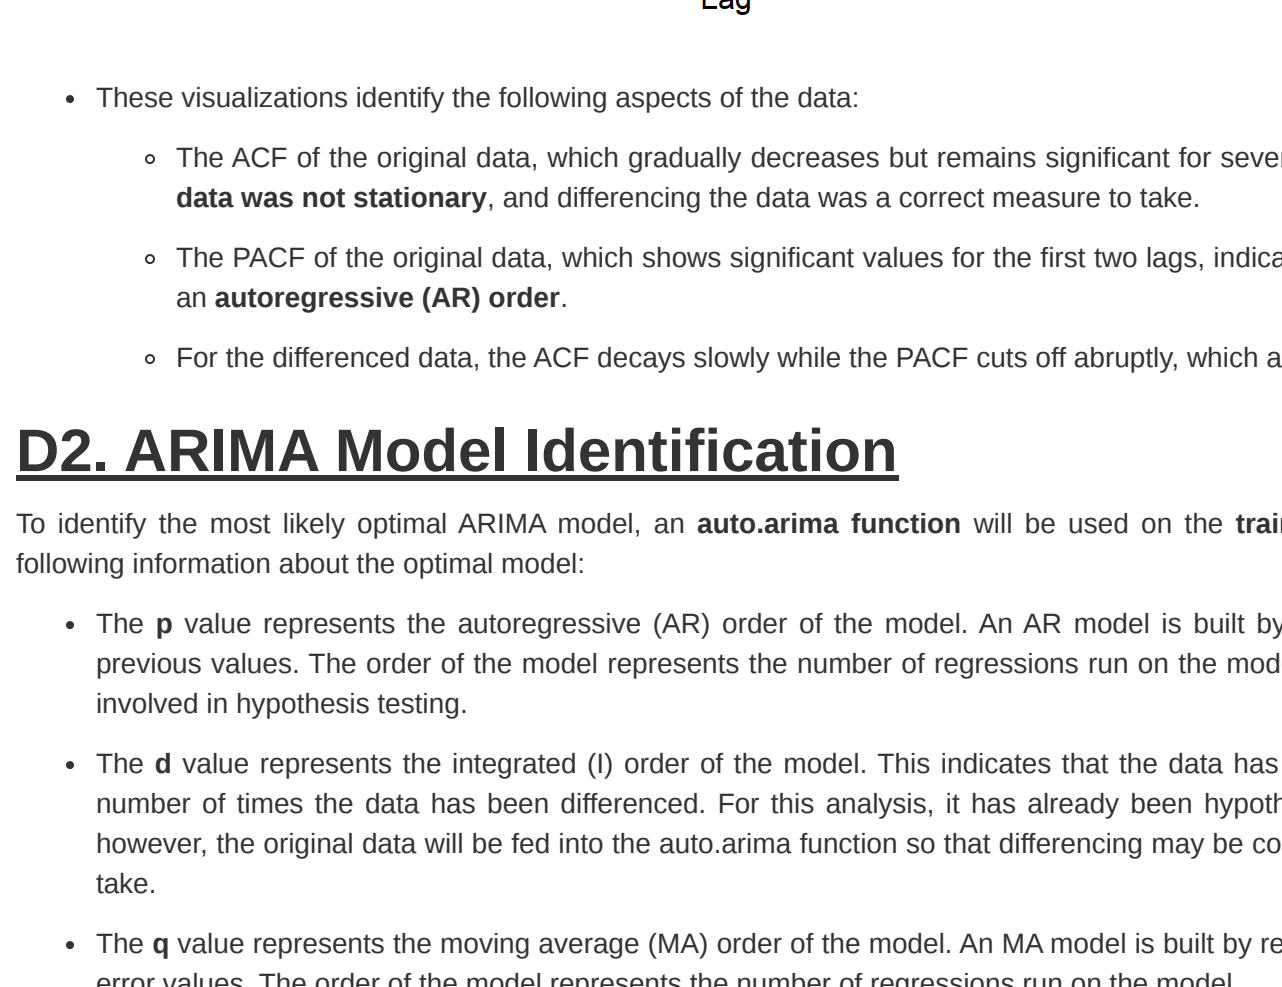

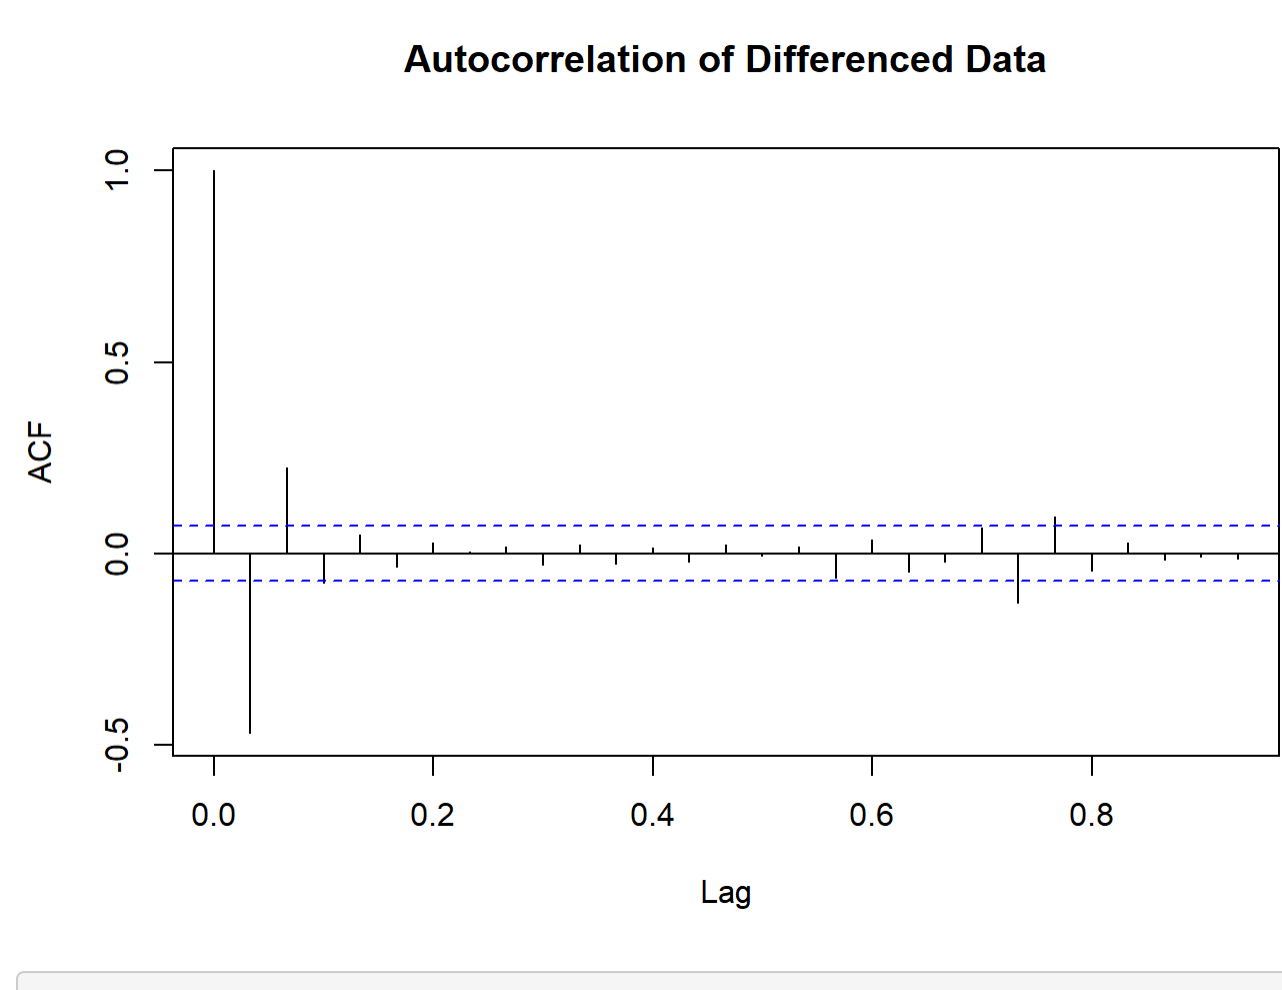

- There is no apparent trend in the spectral density, and the function eventually stabilizes near zero. This indicates there is no apparent seasonality in the data.
- The autocorrelation and partial autocorrelation functions will be examined for both the original data and the differenced data.

```
# autocorrelation function and partial autocorrelation function of differenced data
acf(ts, main = "Autocorrelation of Original Data")
pacf(ts, main = "Partial Autocorrelation of Original Data")

# Autocorrelation of Original Data

# Partial Autocorrelation of Original Data
```

- These visualizations identify the following aspects of the data:
- The ACF of the original data, which gradually decreases but remains significant for several lags, appears to confirm that the original data was not stationary, and differencing the data was a correct measure to take.
- The PACF of the original data, which shows significant values for the first two lags, indicates that the eventual ARIMA model will have an autoregressive (AR) order.
- For the differenced data, the ACF decays slowly while the PACF cuts off abruptly, which also implies an AR model of 1st best.

D2. ARIMA Model Identification

To identify the most likely optimal ARIMA model, an auto.arima function will be used on the training time series data. This will provide the following information about the optimal model:

- The p value represents the autoregressive (AR) order of the model. An AR model is built by regressing individual observations on their previous values. The order of the model represents the number of regressors run on the model. This p value is separate from the p-value included in hypothesis testing.
- The d value represents the integrated (I) order of the model. This indicates that the data has been differenced. The value represents the number of times the data has been differenced. For this analysis, it has already been hypothesized that the data should be differenced; however, the original data will be fed into the auto.arima function so that differencing may be confirmed to have been the correct measure to take.
- The q value represents the moving average (MA) order of the model. An MA model is built by regressing individual observations on previous error values. The order of the model represents the number of regressors run on the model.
- An ARIMA model may or may not be conducted with drift, which represents a constant value added into the regression model.
- An ARIMA model is described by its p, d, and q values in the manner ARIMA(p,d,q).

The results of the auto.arima function are summarized as follows:

```
# Finds optimal ARIMA model
auto.arima(train)

# Series: train
# ARIMA(1,1,0) with drift
# AIC:
# Coefficients: drift
# -0.4597 0.0234
# s.e.: 0.4597 0.0232
# Adjusted R-squared: 0.2187 Lag length used: 385
# AIC: 773.89 AICc: 773.93 BIC: 787

# The model identified as the optimal ARIMA model is ARIMA(1,1,0) with drift. The fit of the model can be described by the Akaike Information Criterion (AIC) score, which is 773.89. This metric can be used to compare different ARIMA models to evaluate their fit for the time series data.
```

To check the results of the auto.arima function, select other ARIMA models will be conducted, with their AIC values measured, to determine whether the designated ARIMA(1,1,0) model will be the best fit for the data.

```
# compares ARIMA models with drift to the ARIMA(1,1,0) model
AR1 <- Arima(train, order = c(1,1,0), include.drift = TRUE)
AR2 <- Arima(train, order = c(0,1,1), include.drift = TRUE)
AR3 <- Arima(train, order = c(2,1,1), include.drift = TRUE)
AR4 <- Arima(train, order = c(1,1,1), include.drift = TRUE)
